False memory susceptibility is correlated with categorisation ability in humans [v2; ref status: indexed, http://f1000r.es/4k0]

Abstract
Our memory is often surprisingly inaccurate, with errors ranging from misremembering minor details of events to generating illusory memories of entire episodes. The pervasiveness of such false memories generates a puzzle: in the face of selection pressure for accuracy of memory, how could such systematic failures have persisted over evolutionary time? It is possible that memory errors are an inevitable by-product of our adaptive memories and that semantic false memories are specifically connected to our ability to learn rules and concepts and to classify objects by category memberships. Here we test this possibility using a standard experimental false memory paradigm and inter-individual variation in verbal categorisation ability. Indeed it turns out that the error scores are significantly negatively correlated, with those individuals scoring fewer errors on the categorisation test being more susceptible to false memory intrusions in a free recall test. A similar trend, though not significant, was observed between individual categorisation ability and false memory susceptibility in a word recognition task. Our results therefore indicate that false memories, to some extent, might be a by-product of our ability to learn rules, categories and concepts.

Introduction
When remembering the past, we typically feel that our memory allows retrieval of events as they really occurred. Yet a large body of work shows that memory is often surprisingly inaccurate, with errors ranging from misremembering minor details of events to generating illusory memories of entire episodes (Loftus, 1997). False memory, the phenomenon of remembering something that actually never occurred, has become a widely studied topic since its origins in Binet’s (1900) La Suggestibilité and Bartlett’s (1932) Remembering. The pervasiveness of such false memories generates an evolutionary puzzle; in the face of selection pressure for accuracy of memory (Dukas, 1999; Mery, 2004; Raine & Chittka, 2008), how could such systematic failures have persisted over evolutionary time? As with perceptual illusions, false memories might be inevitable by-products of otherwise adaptive cognitive processes. Here we explore whether individuals with a higher propensity to form false memories are better at other cognitive tasks, thus generating a trade-off by which certain cognitive capacities (in this case forming links between distinct memories, as in categorisation) cannot be achieved without the cost of memory inaccuracies. A plethora of experimental paradigms exist for eliciting differing types of false memories in declarative memory, i.e. people’s conscious memory for facts (Brainerd & Reyna, 2005). Episodic (and as such autobiographical) false memories are commonly elicited using the misinformation paradigm, in which information provided or questions asked after an event can bias memory (Loftus, 2005). Conversely, semantic false memories can be elicited using the presentation of lists of semantically related words (Deese, 1959; Roediger & McDermott, 1995). The so called Deese-Roediger-McDermott (DRM) paradigm has become widely used for exploring the malleability of memory. In this paradigm, participants begin by studying lists of words; for example a list may comprise the words mad, fear, hate, rage, temper, fury, ire, wrath, happy, fight, hatred, mean, calm, emotion, enrage. Each list is composed of the 15 strongest associates of one critically non-presented word, for example anger for the above list. Upon free recall of the lists or during a recognition test, the non-presented words are ‘remembered’ at high rates and with high levels of confidence. This high proportion of false memories is attributed to the strength of the associations between the words presented in the lists and the words falsely remembered (Deese, 1959).

While such tests might be viewed as rather remote from real-life situations in which the accuracy of memory matters, including episodic memories (DePrince et al., 2004; Freydy & Gleaves, 1996), it has recently been proposed that different types of false memories may share, at least in part, the same underlying mechanisms (Otgaar et al., 2012; Zhu et al., 2013). Otgaar et al., (2012) showed that children who generate a rich false memory when subjected to a typical false memory implantation paradigm, such as being led to believe they once took a ride in a hot air balloon (which in fact never occurred), are also more susceptible to false memories in a DRM test than children who do not develop a rich implanted false memory. Thus the DRM paradigm, artificial though it may seem, can be a useful laboratory paradigm to test individual false memory susceptibility more generally (but see Ost et al., 2013).

False memories, like other memory inaccuracies (such as forgetting) might be by-products of the otherwise adaptive nature of memory processes (Howe et al., 2013; Schacter, 1999; Schacter & Dodson, 2001; Schacter et al., 2011). But what cognitive processes might facilitate the generation of false memories as a by-product? It is possible that our abilities for rule learning, association and categorisation might come at a cost when it comes to memorising isolated facts, events, or indeed words. Specifically with respect to the semantic false memories tested in the DRM paradigm, errors might be produced by the ability of individuals to group words together, placing them in categories based on rules for membership. It therefore seems plausible that the creation of these semantic false memories may be a by-product of our ability to group words into categories. Categorising items is known to generate adaptive benefits such as the ability to learn information more quickly and to show greater efficiency during decision-making (Merritt et al., 2010), but McClelland (1995) argues that whilst such categorisation “is central to our ability to act intelligently” it however “gives rise to distortion as an inherent by-product” (p. 84). It is therefore possible that some memory errors are an inevitable fluke of a powerful, adaptive cognitive phenomenon, in the case of semantic false memories our ability to learn rules and concepts, and to classify novel objects by category memberships (Carey, 2011; Chittka & Jensen, 2011). Indeed, categorisation is a strategy to economise on memory, since it allows recognising objects by a limited set of features that define the category, rather than memorising every single possible member of the category (Avarguès-Weber et al., 2011; Chittka & Niven, 2009; Srinivasan, 2006).

One possibility to explore the potential trade-off between categorisation ability and false memory susceptibility is to exploit variation between individuals, and to test whether superior performance on the one test comes with increased error rates on the other. Inter-individual variation is the raw material for evolution, and offers the possibility to quantify the fitness benefits of cognitive traits in natural settings (Cole et al., 2012; Raine & Chittka, 2008; Rowe & Healy, 2014; Thornton et al., 2014) and to test potential trade-offs between one cognitive capacity and another (Boogert et al., 2011; Raine & Chittka, 2012). Here we investigate a potential correlation between an individual’s proneness to semantic type false memories and their categorisation ability. For this purpose we subjected participants to a DRM paradigm to assess their semantic false memory susceptibility and a test consisting of verbal reasoning questions to assess their ability to form categories. Our findings indicate that false memories, to some extent, might be a by-product of our ability to learn rules, categories and concepts.

Methods
The general method for eliciting false memories was based on Roediger & McDermott (1995) and Stadler et al., (1999). The protocol for the visual presentation of the wordlists was adapted

Participants
Thirty-nine 2nd year undergraduate students from the School of Biological & Chemical Sciences, Queen Mary University of London participated in the study. The participants were one full class undertaking a ‘statistics’ module and as such the experiment formed part of their learning, with a report writing task set from the results. Participant demographics were as follows: seven male, thirty-two female, aged nineteen to thirty years. Full ethics approval was obtained from Queen Mary University of London Research Ethics Committee (Ref #0355) and all participants gave written consent of their acceptance to participate in the study.

Materials
To elicit the false memories, eighteen wordlists were used. Each wordlist consisted of the fifteen most commonly associated words of a critical non-presented word. For example the list mad, fear, hate, rage, temper, fury, ire, wrath, happy, fight, hatred, mean, calm, emotion, enrage is composed of the fifteen strongest associates of the word anger and whilst the fifteen words in the list were shown to participants, the critical word anger was not.

The wordlists were constructed using the first fifteen words listed in the Russell & Jenkins, (1954) norms for the critical non-presented words (see Roediger & McDermott, 1995; Stadler et al., 1999 for full details of list construction). The eighteen wordlists were chosen for their known ability to elicit a high proportion of false memories during recall (Stadler et al., 1999). The eighteen critical non-presented words used (and their corresponding fifteen wordlists) were: window, sleep, smell, doctor, sweet, chair, smoke, rough, needle, anger, trash, soft, city, cup, cold, mountain, slow, river (Stadler et al., 1999).

The wordlists were put into an automated computerised visual presentation containing the eighteen wordlists on a large screen (240cm width, 180cm height). At the end of each list a two minute recall period was given. During these free recall periods, participants were instructed to write down as many of the words from the list they had just seen as they could remember. Participants were instructed not to guess, but to only write down words that they were reasonably sure they had seen. Participants were provided with a booklet in which to write down their responses.

Participants then undertook the recognition test. They were instructed to carefully read the words on the sheet provided and to circle any words that they remembered being presented in the eighteen wordlists. Again participants were instructed not to guess but to only circle words they were reasonably sure they had seen.

After the final recall period a ten minute break was given, but participants were instructed not to talk to each other about the study. Participants were then given seven minutes to work through the categorisation test. Again they were instructed not to guess, but to only answer those questions to whose answer they were reasonably sure of. Upon completion participants were fully de-briefed as to the purpose of the study.

Data analysis
The number of critical non-presented words recalled (false memories), the number of critical non-presented words recognised (false memories), and the number of errors made on the categorisation test were calculated for each individual. These were also converted to give percentage errors (out of those possible to produce) to display graphically. We tested the data for normality and found that the distribution for both the categorisation test and the recognition
false memory test departed significantly from a normal distribution (Shapiro-Wilk normality test). Therefore a non-parametric correlation analysis (Spearman’s rank correlation coefficient) was used to look for a potential link between categorisation ability (categorisation test errors) and false memory susceptibility (recall and recognition errors). Additional correlations were used on subsets of the data to check for any biasing effects of priming, outliers and age. Finally, the numbers of recall, recognition and categorisation errors were compared between males and females using Wilcoxon rank sum tests to look for an effect of gender. All analyses were carried out using R statistical software (v.2.14.1). P values below 0.05 were deemed significant.

Individuals’ susceptibilities to false memories elicited using the Deese-Roediger-McDermott (DRM) paradigm (given as the number of critical non-presented words recalled (Recall False memories, out of a total of 18) and recognised (Recognition False Memories, again out of 18)), and their categorisation abilities (given as the number of questions answered incorrectly on the categorisation test (Categorisation Test Errors, out of a total of 45)).

There were substantial inter-individual differences in both participants’ verbal categorisation abilities and their scores on a standardised false memory test. Categorisation errors ranged from 7% to 78% in different individuals (Mean 23%, SD 14%), showing that even though the test we had chosen was originally designed for pre-teens, the task was sufficiently challenging for the tested population to capture a large range of inter-individual variation (Figure 1a). It was important to establish this since if all participants had near-perfect scores (or indeed if all had equally poor scores), the test would not have been suitable to correlate individual variation with other assessments of cognitive performance.

Variation in individual false memory scores was likewise extensive. Recall false memory scores ranged from 0% to 78% (Mean 41%, SD 21%) of possible false memories made (Figure 1b). Two individuals did not recall a single critical non-presented word and thus had a score of zero (and 0%) for recall false memories. Conversely three individuals recalled thirteen out of the possible eighteen false memories (and thus scored 72%), and one participant even scored fourteen (78%). Recognition false memory scores ranged from 17% to 94% (Mean 63%, SD 21%) of possible false memories made (Figure 1c). Five individuals recognised five or less of the critical non-presented words (and thus scored 28% or less), whilst eighteen individuals recognised thirteen or more out of the eighteen possible false memories (and thus scored 72% or more).

Figure 1. Frequency histograms of individual variation in categorisation ability and false memory performance. a) the percentage of errors scored by individuals on the categorisation test. b) the percentage of false memories (out of those possible to elicit) recalled by individuals during the DRM paradigm and c) the percentage of false memories (out of those possible to elicit) recognised by individuals during the DRM paradigm. N=39. All show a spread of inter-individual variation.
We found a significant negative correlation between individuals’ categorisation error scores (given as the number of questions answered incorrectly on the categorisation test) and their false memory susceptibility during free recall (given as the number of critical non-presented words recalled) \((r_s=-0.345, df=37, p=0.032, \text{Figure 2})\), thus those individuals scoring fewer errors on the categorisation test were more susceptible to false memory intrusions during free recall. In other words, participants that performed worse on the one test performed better on the other, and vice versa – indicating an inter-individual trade-off between categorisation ability on the one hand and false memory susceptibility during free recall on the other.

We also found a slight negative correlation between individuals’ categorisation error scores (given as the number of questions answered incorrectly on the categorisation test) and their false memory susceptibility during recognition (given as the number of critical non-presented words recognised); however this trend was not significant \((r_s=-0.202, df=37, p=0.219, \text{Figure 3})\).

To exclude the possibility that any correlation could be caused by priming, the data were also analysed excluding those categorisation test questions that contained words previously presented in the wordlists, and non-presented as one of the critical non-presented words. In our experiment for example, priming may have meant that the word eye presented as part of a question in the categorisation test: 41. Eye neck nose mouth shoulder, may have been preferentially selected as an answer due to its previous presentation in the word list associated with the critical non-presented word needle – thread, pin, eye, sewing, sharp, point, prick, thimble, haystack, thorn, hurt, injection, syringe, cloth, knitting. As such the scores for twelve questions were removed. A significant negative correlation was still found for free recall and a moderate negative, though non-significant, correlation found for recognition; thus priming cannot account for the result (recall: \(r_s=-0.362, df=37, p=0.024\), recognition: \(r_s=-0.206, df=37, p=0.208\)).

Additionally, the removal of an outlier (a residuals vs. leverage plot showed a Cook’s distance greater than 0.5 for participant 24, see Dataset 1) did not change the statistical significance of the original result, thus it was not skewing the data unnecessarily in one direction and was therefore not the cause of the significant negative correlation found (recall: \(r_s=-0.341, df=36, p=0.036\), recognition: \(r_s=-0.175, df=36, p=0.293\)).

The ages of the participants were not greatly varied, with thirty-six out of thirty-nine participants aged nineteen to twenty-one, one participant aged twenty-three, one participant aged thirty and one participant not stating their age. The removal of the data for the participant aged thirty did not change the statistical significance of the original result, thus the greater age of this participant in comparison to the others was also not the cause of the significant negative correlation found (recall: \(r_s=-0.387, df=36, p=0.016\), recognition: \(r_s=-0.251, df=36, p=0.129\)). Furthermore, the imbalance in the number of male and female participants (seven male, thirty-two female)
is unlikely to have caused any bias in the data as there was no significant difference between the two genders in the mean values for the recall errors (Wilcoxon rank sum test: W=114, p=0.956), recognition errors (Wilcoxon rank sum test: W=97.5, p=0.605) nor the categorisation test scores (Wilcoxon rank sum test: W=102, p=0.727).

Discussion

Our findings show a trade-off between word categorisation ability and semantic false memory susceptibility, so that individuals that make more errors on the false memory test make fewer errors on the categorisation test, and vice versa. Thus our results cannot simply be explained by differences in level of education, literacy, vocabulary or intelligence. If such an underlying factor would have explained performance on both tasks, then superior performance on one task would have been a predictor of superior performance on the other task. For example, short term memorisation of word lists recruits working memory, which is often regarded as a general predictor of intelligence (Oberauer et al., 2005; Oberauer et al., 2008) and likewise the categorisation tests used here are typical components of standardised intelligence tests (Wechsler, 2004; Wechsler, 2008). Thus one might have predicted a positive correlation of error scores in both tasks if an underlying single factor such as intelligence would explain the data. However, the correlation of error scores in the two measured tasks was negative. Thus even though this study is clearly correlative in nature, and therefore does not allow us to conclude with certainty that the two performances are based on the same underlying mechanisms, it is intriguing that having a lower tendency to generate false memories comes at a cost, i.e. lower categorisation scores.

To date the majority of scholars interested in false memories have focused on factors which may exacerbate or reduce the occurrence of such memory errors (Dodson et al., 2000). The adaptive nature of the human memory system as a potential reason for the occurrence false memories has been suggested (Schacter, 1999; Schacter, 2001), yet the ultimate reasons for their existence has been infrequently explored empirically. More recently, however, evidence has grown for links between individuals’ differing susceptibilities to false memories and their variations in a range of cognitive features. False recall and/or recognition rates in a DRM paradigm have been shown to vary with individuals’ variations in levels of vivid mental imagery (Winograd et al., 1998), specific area expertise (Baird, 2003; Castel et al., 2007), working memory capacity (Watson et al., 2005) and need for cognition (the degree to which an individual actively engages in cognitive tasks) (Graham, 2007).

Additionally it has been shown that when survival-related (i.e. evolutionarily relevant) information is used in a list-learning paradigm, increased susceptibility to false memories occurs. Howe & Derbish, (2010) found that when participants are asked to process words for their survival value and when the words presented were themselves survival relevant (i.e., ‘death: burial, casket, cemetery; funeral, grave, life, murder, suicide, tragedy, widow), veridical and false recognition were significantly higher (leading to an overall decrease in net accuracy) than when the words viewed were neutral or negative and were processed for pleasantness. They concluded that whilst it does not at first seem adaptive for survival-related memories to be less accurate and in fact be more prone to false intrusions than other types of memory, it does make sense if considered as a by-product of the adaptive processing of information related to survival. Howe & Derbish (2010) argue that during the processing of information related to survival, any related information in memory is then primed, which may or may not be false, but that this information is then used to guide attention to other survival-related items, which may be crucial in the current situation (Howe & Derbish, 2010).

It has even been postulated that this greater inaccuracy may actually have adaptive significance, being more helpful in real-world scenarios. For example, in responses to predation threat, false alarms, such as generalising to a large set of cues that might indicate predator presence are clearly less detrimental errors than missing predator presence based on interpreting predators’ cues too narrowly (Howe & Derbish, 2010). Thus our finding of a significant positive correlation between susceptibility to semantic false memories in a free recall DRM paradigm and word-based categorisation ability, with the creation of these errors a by-product of our ability to group words, is in keeping with recent explorations of the adaptive conditions related to the phenomenon of false memories.

Whilst the age range of the subjects tested was narrow (nineteen to twenty-one years old in the majority) many of the key studies using the DRM paradigm have used only participants also of average undergraduate college study age (Roediger & McDermott, 1995; Stadler et al., 1999). Additionally the only significant difference in spontaneous false memory creation, caused by the DRM paradigm that is known to occur between participants of different ages, is between children and adults. Several studies have shown that children are less prone to these memory errors, with an increase in their propensity occurring during both childhood and early adolescence (Brainerd et al., 2002; Brainerd et al., 2004; Forrest, 2002). As such, inferences made from our findings are not just applicable to young adults but should also be pertinent to the ‘average’ adult population as a whole.

Our result of a significant negative correlation between individuals’ errors on a categorisation test and their susceptibilities to semantic type false memories during free recall demonstrates that false memories, to some extent, might be a by-product of our ability to learn rules, categories and concepts. For example, once we have learnt the concept/category of mammals, we can identify new animals as members of this category even if we have never seen them before. In this case, labelling the new animal as mammal is not based on false classification, but a correct one based on category membership: the simple flipside of the DRM paradigm, where inferences based on concepts and categories are classed as errors. Thus, our findings add to the increasing body of literature that proposes that some types of false memories might be an inevitable by-product of adaptive cognitive processes as is the case with other memory aberrations (Abbott & Sherratt, 2011; Beck & Forstmeier, 2007; Newman & Lindsay, 2009).

References

In this paper, Hunt and Chittka show that people who are better at a categorization task also tend to produce more "memory errors" on the DRM paradigm, in which 15 words are shown which are strongly associated with a non-presented word (which is then often (wrongly) recalled or recognized later by the participants). The experiment has been conducted properly (the issue of counterbalancing has been addressed by the priming re-analysis) and the results are clear, although the effect size does not seem large.

The conclusions the authors draw from this result seem eminently reasonable, although they may go a bit beyond the immediate data. After all, they specifically picked a form of false-memory testing that relies heavily on the fact that words in a semantic category are tightly associated with each other. It is then not a great surprise that people who are good at keeping words from the same semantic categories together also show more memory errors. It might have been interesting to ask people to categorize on different criteria than semantic (e.g. based on the letters they contain). Even though this is still a test of finding odd words out in a group, it does not call on semantic categories...

The introduction is probably setting up a bit of a straw man. I think false memories as discussed here should be limited to those in episodic memory. Even the DRM is an episodic memory task (recall the unique list you've just been presented with), which is influenced by semantic associations between words. Therefore, any discussion of selective pressures on memory accuracy should be based on episodic memory alone. And there are lots of debates about what episodic memory is for, and indeed whether accuracy is the most important part of episodic memories. False memories in episodic memories often come about by "intrusion" of more common events into a unique episode. If the common events are that common, the unique exception may not be important to remember and indeed may interfere with the (adaptive) application of a learned rule. So there may be many arguments against the idea that memory should always be accurate. Nevertheless, this does not take away from the data or the final conclusions of this paper.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

We thank the referee for the constructive comments. We agree with the referee that one function of cognition (probably not just episodic memory) is to extract commonalities between distinct individual memories, learn rules, and to categorise objects and events by common properties, and to classify novel objects or events into existing frameworks. Certainly such rule-learning and classification abilities are adaptive, and we have thus deleted the statement that “false memories cannot in themselves be useful”.

Nonetheless, it is probably fair to say that many of the contexts in which false memories occur ‘naturally’, as well as the common experimental paradigms (not just ours), rely on rule learning and classification abilities. Witnesses of a nocturnal street robbery might describe the perpetrator as a hooded teenager, when it later turns out that the assailant was middle-aged and balding. While such false memories create enormous difficulties for the police and criminal courts, the witnesses may have made of use of their (typically, but clearly not always, adaptive) ability to learn rules about settings or conditions that, at least potentially, indicate danger. From the earliest explorations of false memories, such as the transmission chain studies in Bartlett’s work, it was investigated how distorted memories fall in with previously memorised rules, cultural norms etc. Whether this means that individuals that are better at extracting common properties incur a cost when it comes to storing large number of individual items/memories is precisely the subject of this study. We agree with the referee that it might sometimes be more useful to memorise common events than individual ones, or indeed to extract the commonalities between events and discard their idiosyncrasies, and this is hopefully clearer in the revised version.

This is an interesting article that has good relevance to ongoing debates on the adaptiveness of memory errors. The methods and analyses are appropriate and the authors have generally represented the scientific literature well. I have a few minor suggestion for improvement, as follows:

In the paragraph beginning “While such tests might be viewed as rather remote from real-life situations..” it should be noted that there are several more studies in which errors in different false memory paradigms are correlated either weakly (e.g., Zhu et al., 2013) or not at all (e.g. Ost et al., 2013).

The line “Clearly false memories cannot in themselves be useful” is disputable – several studies now show positive consequences of distorted memories, see e.g. Howe, Garner & Patel, 2013; Bernstein & Loftus, 2009).

Line “It is therefore possible that memory errors are an inevitable fluke of a powerful, adaptive cognitive phenomenon” – I would prefer to say “some memory errors” – there is a broad literature on other adaptive reasons why memory errors occur, see e.g. Newman & Lindsay (2009). Same point applies to the very final sentence of the Discussion.
Why wasn't the order of the two tasks counterbalanced? Is it plausible that the first (memory) task might have primed a particular mindset in participants that affected their categorization performance? I’d suggest the addition of a little discussion of this point.

Data analysis – which data departed from normality? The authors have reported a normality test but it isn’t clear to which variable this test pertains.

The line “A significant negative correlation was still found for free recall and a moderate negative correlation still found for recognition” – the authors should reiterate explicitly that the latter correlation was non-significant.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

**Lars Chittka**, School of Biological and Chemical Sciences, Queen Mary, University of London, UK

We thank the referee for the constructive comments. We have taken all of them on board in the revised version. We have also added the five additional references indicated by the referee, and modified the text in line with the contents of these publications. We have added the requested information about non-normality of some of the data.

The referee asks why we have not used a counterbalanced design, so that in addition to setting the false memory test first and the categorisation test second, we might have reversed the order. This would indeed be a useful procedure to exclude the possibility that any correlation could be caused by priming, occurring as a result of words occurring in both tests. However, to address the potential complication of priming, we had already reanalysed the data excluding those categorisation test questions that contained words previously presented in the DRM word lists, and non-presented as one of the critical non-presented words. However, even after removal of all individual tasks where such words occurred, the overall results remained unaltered (see results section).

**Competing Interests:** No competing interests.
